SPECIFIC VOLUME AND VISCOSITY OF ETHANOL-WATER MIXTURES UNDER HIGH PRESSURE

By Yoshiyuki Tanaka, Takeshi Yamamoto, Yoshimasa Satomi, Hironobu Kubota and Tadashi Makita

The specific volume and the viscosity of enthanol-water mixtures at 25° (298.15K) and 50°C (323.15K) have been measured under pressures up to 3200 and 800 bar (10⁵Pa), respectively. The measurements were performed by a modified Adams piezometer and a falling-cylinder viscometer. The maximum uncertainties are estimated to be 0.05% for the specific volume and 2% for the viscosity.

The specific volume of the pure components and their mixtures is found to decrease monotonously with increasing pressure. The results obtained are compared with several sets of literature values. The numerical data at each temperature and composition are correlated satisfactorily as a function of pressure by both polynomial and the Tait equations. It is also found that a definite minimum appears on the isothermal compressibility versus composition isobars, arising from the complex interactions between hydrogen-bonded water and alcohol molecules.

The viscosity of pure ethanol and mixtures is found to increase almost linearly with increasing pressure, whereas that of water is nearly independent of pressure in these experimental conditions. The viscosity isotherms can be formulated by a quadratic equation of pressure within the experimental error. As for the composition dependence of the viscosity, a distinct maximum appears near 0.3 mole fraction of ethanol on all isobars at both experimental temperatures.

Introduction

The physico-chemical properties of aqueous solutions of alcohols are of interest in many fields of science. The solutions often show some anomalies in various physical properties such as partial molar volume, compressibility, velocity of sound, sound absorption, viscosity and so on, which have been yet inadequately understood. Such properties of mixtures in a wide region of temperature and pressure are important both in chemical engineering designs and in theoretical investigations of excess thermodynamic properties. However there have been only a few measurements on these properties, especially under high pressure.

The present investigation was undertaken to provide extensive and accurate P-V-T and viscosity data under high pressure for ethanol-water mixtures. Numerical data have been determined at 25° and 50°C under pressures up to 3200 bar for specific volume and 800 bar for viscosity, employing a modified Adams piezometer and a falling-cylinder viscometer. Empirical correlation formulas have also been presented for both properties from the experimental results.

Experimentals

P-V-T measurements

The specific volume of the ethanol-water mixtures has been measured by a modified Adams piezometer¹⁾ similar to that used by Newitt et al.²⁾ The piezometer is made of Pyrex glass. The schematic diagram is given in Fig. 1 and the typical dimensions are summarized in Table 1. The volumes of the piezometer and the capillary stem were determined by weighing them filled with distilled water or mercury. The piezometer was set in a high pressure vessel equipped with a pair of optical windows which enable us to observe and control precisely the mercury level in the capillary stem. The high pressure vessel was immersed in a thermostat bath controlled within ± 0.01 °C. The pressure was measured by Heise Bourdon gauges calibrated against a pressure balance. The uncertainty in pressure measurements is estimated to be less than 0.1%.

The mercury trapped in the piezometer was washed with ethanol and weighed after drying.

Table 1 Dimensions of Instruments used

The specific volume of the sample liquid was calculated by the following equation:

Density

 $v = \frac{V_0 (1 - k_{\rm g}) - V_0 (1 - k_{\rm g}) - (W_{\rm Hg}/\rho_{\rm Hg})}{V_0 \rho_0}$ (1)

where

: specific volume of the liquid at P bar in cm³·g⁻¹.

 V_0 : inner volume of the piezometer at 1bar in cm³.

 $V_{\rm c}$: inner volume of the capillary at 1bar in cm³.

 $W_{\rm Hg}$: weight of mercury trapped in g.

 ρ_0 : density of the liquid at 1bar in g-cm⁻³,

 $\rho_{\rm Hg}$: density of mercury at P bar in g·cm⁻³.

 k_g : compression of Pyrex glass at P bar.

The values of $k_{\rm g}$ and $\rho_{\rm Hg}$ were cited from the results of Adams¹⁾ and Grindley *et al.*,³⁾ respectively. The densities of mixtures under the atmospheric pressure were determined experimentally by a pycnometer and partly cited from the handbook.⁴⁾

Viscosity measurements

The viscosity has been measured by a falling-cylinder viscometer. The viscosity was determined principally based on the Stokes law on a rigid sphere falling in an infinite homogeneous fluid. The details of the theoretical basis are described by Swift *et al.*5-7)

The schematic diagram of the viscometer employed is given in Fig. 2. The apparatus consists of a precisely bored Pyrex glass tube equipped coaxially in a high pressure vessel and a glass cylind-

rical plummet with hemispherical ends. The instrument dimensions are listed in Table 1. A sample liquid was introduced into both sides of the glass tube through a fine flexible pipe made of stainless steel. The plummet is provided with four small projecting lugs at each end of the cylindrical part, which act as a guide to keep the plummet concentric when it falls. The falling time of the plummet was determined within ± 0.1 ms by an electronic time-interval counter with the aids of a He-Ne gas laser beam passed through a pair of optical windows and a phototransister. The viscometer could be rotated on a horizontal axis in order to return the plummet to its starting position. The temperature of the sample was maintained constant within $\pm 0.05^{\circ}$ C by circulating a thermostatic fluid through the jacket around the pressure vessel and measured by a thermister device. The pressure was measured by a Bourdon gauge with the same accuracy as the case of P-V-T measurements. The falling time ranged from 5 to 20 seconds according to the change of the viscosity of samples and was measured about 20 times at each experimental condition. The mean reproducibility of the falling time is within 0.5%. The arithmetic mean values were taken as the final values.

Due to the geometric effect of the plummet and the wall effect of the glass tube, the Stokes law is not valid strictly for a falling-body other than a rigid sphere in an infinite homogeneous fluid. Therefore, the calibration of the present viscometer is required with fluids of known viscosity. The basic equation of the falling-body viscometer is as follows:

$$\gamma = K(\rho_1 - \rho)t \tag{2}$$

where

 η : viscosity of a liquid at P bar in 10⁻³Pa·s, ρ : density of a liquid at P bar in g·cm⁻³,

 $\rho_{\rm b}$: density of the plummet at P bar in g·cm⁻³.

t: falling time in s.

The instrument constant K and its change with both temperature and pressure were determined based on the experimental viscosity values under the atmospheric pressure obtained by an Ostwald viscometer and the standard viscosity values of water correlated by the International Association for the Properties of Steam.⁸⁾ The densities of mixtures were calculated from Eq. (3) obtained in the present work. When the resistance factor⁵⁾ is plotted against the Reynolds number in logarithmic coordinates, the calibration curve is found to be a straight line with a slope of about -1. This means that each measurement was carried out in a laminar flow region with lower Reynolds numbers than 0.5 throughout the experimental condition.

Materials

Extra pure ethanol was obtained from Wako Pure Chemical Industries, Ltd. The reported purity is more than 99.5% in volume. Ethanol and water were purified several times by the fractional distillation. The mixtures of ethanol and water were prepared by weighing, using an analytical balance with a sensitivity of $\pm 0.1 \text{mg}$. Therefore their composition, mole fraction of ethanol, should

⁸⁾ International Association for the Properties of Steam, "Dynamic Viscosity of Water Substance"
The Eighth International Conference on the Properties of Steam, Giens, France (1974)

be substantially accurate within 0.01%.

Uncertainty of experimental results

The numerical data of the specific volume and the viscosity obtained contain a definite uncertainty resulting from several sources of experimental errors. The main sources and their portions in the final values are estimated as follows:

(Specific volume measurement)

| Error source | Uncertainty contributing to v |
|------------------------|-------------------------------|
| Temperature | ±0.001% |
| Pressure | ±0.01% |
| Composition of mixture | ±0.01% |
| Piezometer volume | ±0.01% |
| | |

(Viscosity Measurement)

| Error source | Uncertainty contributing to 7 |
|------------------------|-------------------------------|
| Temperature | ±0.1% |
| Pressure | ±0.01% |
| Composition of mixture | ±0.02% |
| Falling time | ±0.5% |
| Density | ±0.01% |
| Instrument constant, K | ±1.0% |

Taking into account the above estimations, the uncertainties probable in the present measurements may be less than 0.05% for the specific volume data and 2.0% for the viscosity data. This fact has been verified satisfactorily by the comparison with the reliable data of pure components by other authors, as partly described below.

Results and Discussions

P-V-T data

Table 2 lists the measured P-V-T relations for ethanol-water mixtures at 25° and 50°C under pressures up to 3200 bar. X is the mole fraction of ethanol in the mixtures. The results are also plotted in Figs. 3 and 4 together with the previously published data for pure water and mixtures for comparison. The specific volume decreases monotonously with increasing pressure throughout the experimental conditions at each composition of mixtures. At 25°C, the present results agree quite well with the values given by Kell et al.99 and Grindley et al.39 for pure water up to 3000 bar and those of Moesveld10 for mixtures up to 1500 bar. However, some discrepancies between the present work and the recent report of Yusa et al.113* are found to be up

to 0.9% at high ethanol mole fractions and high pressures. As for 50°C, the present results for pure water are in good agreement with the values of Kell et al.9) and Grindley et al.3) However, there exists no data on mixtures available in literature for direct comparison with the present work.

Specific Volume and Viscosity of Ethanol-Water Mixtures under High Pressure

and the Tait equation:

$$\frac{v_o - v}{v_o} = C \log \left(\frac{B + P}{B + 1} \right) \tag{4}$$

where v_0 is the specific volume at the atmospheric pressure and P the pressure in bar. The empirical coefficients were determined by the least squares method as given in Tables 3 and 4 together with the average and the maximum deviations of the experimental data from the formulas. Although the polynomial equation gives a better fit to the data in general, the isothermal compressibility

$$\dot{\beta}T = -\frac{1}{v} \left(\frac{\partial v}{\partial P}\right)_T \tag{5}$$

is calculated by the Tait equation because the polynomial equation sometimes gives unexpected behaviors by the differentiation. The functional dependences of the isothermal compressibility on composition are shown in Figs. 5 and 6 at 25° and 50° C, respectively. It is found that a definite minimum exists near x=0.1 on the lower pressure isobars than 2000 bar. As well known in the case of pure water, the isothermal compressibility has a minimum near 50° C on the isobars lower than 2000 bar. This anomaly could be seen in the range of low ethanol composition, and disappears with increasing composition near x=0.2, where the isothermal compressibility is independent of temperature under each pressure. Furthermore, it seems that another inflection might occur at higher mole fraction of ethanol near x=0.7 on the low pressure isobars. (Concerning this second inflection, more detailed experimental results will be reported in the near future.) Yusa et al., (1) have found the similar

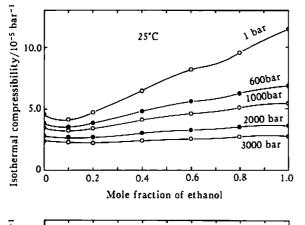

Fig. 5 Composition dependence of the isothermal compressibility of ethanol-water mixtures at 25°C under high pressure

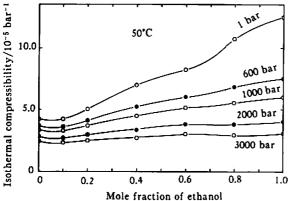

Fig. 6 Composition dependence of the isothermal compressibility of ethanol-water mixtures at 50°C under high pressure

phenomenon in his isothermal compression versus composition isobars. These anomaly would be attributed to complex interactions between the hydrogen-bonded water and the bifunctional nature of alcohol molecules. 12.13)

Viscosity

The viscosity of ethanol-water mixtures has been measured at 25° and 50°C up to 800 bar. The raw data are tabulated in Table 5. Values of the viscosity obtained at the atmospheric pressure are compared as a function of composition to other data available in literature¹⁴⁻²²⁾ in Fig. 7. The vis-

cosity data display a maximum at a composition from 0.2 to 0.3 mole fraction of ethanol at each temperature. Agreement of the data among researchers is comparatively good at 25°C, except the

Y. Tanaka, T. Yamamoto, Y. Satomi, H. Kubota and T. Makita

results reported by Yusa et al., 11) whose data are about 4% higher than others near the maximum. Inconsistency of the data is found to increase at 50° C, where the largest deviation between the data of Sabnis¹⁸⁾ and those of Traube¹⁴⁾ is about 13% near x=0.2.

The viscosity data obtained at high pressures are also compared with those in literatures. The pressure effects on the viscosity are shown in Figs. 8 and 9 together with the results of Abaszade et al.²²⁾ and Yusa et al.¹¹⁾ for mixtures and those of Golubev et al.²³⁾ for pure ethanol. Figs. 8 and 9 include partly interpolated data to the same compositions by a graphical method, because the previous data under pressures available for a direct comparison are limitted. It is found that agreement among the four sets of data is rather good at low pressures, but that the discrepancy increases with increasing pressure. A serious inconsistency is found in the results for pure ethanol. In the results of Yusa et

²³⁾ I. F. Golubev and V. A. Petrov, Trudy GIAP, No. 2, 5 (1953)

 $al.,^{11)}$ the pressure coefficient of viscosity, $\left(\frac{\partial \eta}{\partial P}\right)_T$ for ethanol is rather small at 25°C, while the data of Golubev et al.23) and the present work give an obvious positive pressure dependences. The viscosity of the mixtures increases almost linearly with pressure, whereas that of water is almost independent of pressure in this pressure range.

The viscosity isotherms in this work can be represented by a quadratic equation of pressure.

$$\gamma = B_1 + B_2 P + B_3 P^2 \tag{6}$$

where η is the viscosity in 10^{-3} Pa·s (=cP) and P the pressure in bar. The coefficients for each mixture are determined by the least squares method and listed in Table 6 with the average and the maximum deviations.

The composition dependence of the viscosity under high pressures is shown in Fig. 10. Each isobar also exhibits a maximum near the composition x=0.3. The maximum shifts slightly to higher ethanol fraction with increasing pressure or temperature.

Conclusion

This paper represents the raw experimental data on the specific volume and the viscosity of ethanol-water mixtures as functions of temperature pressure and composition. This basic information would be necessary to solve the complicated behavior of aqeous solutions of hydroxycompounds, which are yet inadequately understood. However, the temperature range is narrow in the present measurements, and more detailed measurements is thought to be needed fully near the composition where the anomaly appears. Furthermore, the relationship between the equilibrium (thermodynamic) properties and the non-equilibrium (transport) properties should be derived, especially as for the appearance of anomalies, as well as in the case of aqueous solutions of other alcohols.
